Cache-Efficient Compilation of PRAM Algorithms via Hash-Partition Locality

Abstract

We present a compiler that transforms PRAM algorithms into both work-optimal and cache-efficient sequential and parallel code, supporting all three memory models (EREW, CREW, CRCW). On a benchmark suite of 51 classic PRAM algorithms spanning 10 algorithmic families, all 51 algorithms (100.0%) meet a 2× cache-miss target versus hand-optimized sequential baselines—up from an initial 44/51 (86.3%) before automated IR repair. Seven algorithms were fixed via automated transformations: Shiloach–Vishkin, Borůvka MST, flashsort, graph coloring, maximal independent set, strongly connected components, and string sorting.

The central theoretical contribution is the **Hash-Partition Locality Theorem**: Siegel k-wise independent hash families [10] partition a PRAM address space of n items into $\lceil n/B \rceil$ cache-line-aligned blocks with maximum per-block overflow $O(\log n/\log\log n)$ with high probability, yielding a cache-miss bound of $O(pT/B + T)$ with constant $c_3 \leq 4$ for a PRAM algorithm with p processors and time T. A **Work-Preservation Lemma** established by structural induction guarantees that the emitted code performs at most $O(pT)$ operations with constant $c_1 \leq 4$ via Brent scheduling and staged partial evaluation. This connects two independently developed lines of research—Siegel's collision-avoiding hashing (designed for PRAM network emulation) and cache-oblivious algorithm design (designed for sequential memory hierarchies [8]).

The compiler is a three-stage pipeline (hash-partition analysis, Brent scheduling with locality ordering, staged code generation) that emits sequential C99, parallel OpenMP C, and an adaptive mode with profile-guided runtime crossover selection. A schedule-level CRCW conflict resolver handles Priority, Arbitrary, and Common write semantics by eliminating redundant writes at the schedule level. An adaptive partitioning engine classifies access patterns (Regular, GraphTraversal, Scattered) and selects block sizes and multi-level strategies accordingly. A hardware counter measurement framework generates CSV benchmark data for all compilation targets. Across the full suite, the average L1 miss rate is 0.77% and the average cache bound ratio is 0.49, with 1,476 tests passing.

1 Introduction

The PRAM (Parallel Random Access Machine) model has served as the standard theoretical foundation for parallel algorithm design since the 1970s [2]. Many algorithms have been developed with tight work and depth bounds: Cole's $O(\log n)$-time merge sort [3], Shiloach–Vishkin connected components [4], Borůvka's parallel minimum spanning tree, and dozens more.

Brent's theorem [1] guarantees that any PRAM algorithm using p processors in T steps can be simulated sequentially in $O(pT)$ operations. However, Brent's theorem says nothing about *cache behavior*. A naïve Brent simulation can scatter memory accesses across the address space, incurring $\Theta(pT)$ cache misses—one per operation—negating the work-optimality advantage on real hardware.

Definition 1 (Brent Gap)**.** *The* Brent gap *is the asymptotic distance between the work guarantee $O(pT)$ (from Brent's theorem) and the cache-miss bound $O(pT/B + T)$ (needed for practical efficiency, where B is the cache-line size in elements).*

Contributions.

1. **Hash-Partition Locality Theorem** (§3): Siegel k-wise independent hashing partitions PRAM addresses into cache-line blocks with $O(\log n/\log\log n)$ overflow w.h.p., yielding a cache-miss bound $Q \leq c_3(pT/B + T)$ with $c_3 \leq 4$ after multi-level partition refinement. Full proof in Appendix A.

2. **Work-Preservation Lemma** (§3): The staged partial evaluator emits code with at most $c_1 \cdot W$ operations where $W = pT$ is the PRAM work and $c_1 \leq 4$, proved by structural induction on the intermediate representation. Full proof in Appendix I.

3. **Three-stage adaptive compiler** (§4): Hash-partition analysis → Brent scheduling with locality ordering → staged code generation. Profile-guided adaptive compilation emits sequential C99, parallel OpenMP C, or adaptive runtime crossover code.

4. **CRCW write-conflict resolution** (§5): A two-level approach handling CRCW-Arbitrary, CRCW-Priority, and CRCW-Common semantics: (a) IR-level write coalescing and priority-write serialization; (b) schedule-level conflict resolution that eliminates redundant writes per (phase, region, address) group.

5. **Adaptive partitioning for irregular access** (§4, §5): An access pattern analyzer classifies address streams as Regular, GraphTraversal, or Scattered, then selects block sizes and multi-level partitioning strategies accordingly. Combined with write-combining buffers for scattered writes.

6. **Automated IR repair** (§5): Five targeted transformations (CRCW coalescing, priority-write serialization, irregular access tiling, loop fusion, write-combining buffers) bring success from 44/51 (86.3%) to 51/51 (100%).

7. **Hardware measurement framework** (§7): A performance counter infrastructure that generates CSV benchmark data for cache simulation and hardware-level evaluation across all compilation targets (sequential, parallel, adaptive).

8. **Comprehensive evaluation** (§7): 51 algorithms, 10 families, 5 hash families, with detailed statistical analysis. Average L1 miss rate: 0.77%. Average cache bound ratio: 0.49. All 1,476 tests pass.

9. **Formal operational semantics** (§8): Small-step semantics for the PRAM IR with explicit CRCW conflict resolution rules (Priority, Arbitrary, Common), enabling executable verification of IR transformations.

10. **Property-based verification** (§9): Exhaustive property testing of the Work-Preservation Lemma across all Stmt/Expr variants, including compositionality, work-bound preservation under partial evaluation, and specialization idempotence. Semantic preservation of IR repair transformations is verified by simulation-based comparison on 100 random inputs per transform, paired with formal *validation witnesses* specifying proof strategy (bisimulation, refinement, or commutativity) and preconditions. Translation validation combines structural invariant checks with semantic equivalence verification. Compositional verification tests that sequential application of multiple passes preserves end-to-end correctness across all memory models.

11. **PGO distributional analysis** (§10): Statistical sensitivity analysis of profile-guided optimization decisions across six input distributions (uniform, sequential, reverse-sorted, strided,

clustered, Zipfian), with Welch's t-test significance testing, confidence intervals for crossover thresholds, per-algorithm crossover detection, and sensitivity ratio reporting.

Significance. The Hash-Partition Locality Theorem establishes a formal connection between Siegel's collision-avoiding hash families (developed for PRAM emulation on parallel networks [10]) and cache-oblivious algorithm design (focused on sequential memory hierarchies [8]). This extends the line of work from NESL [5] (which achieves work-efficiency but not cache-efficiency) and Cilk [7] (which provides cache bounds for work-stealing but not for general PRAM serialization) by providing cache-miss guarantees for the full range of PRAM memory models, including CRCW with arbitrary and priority conflict resolution.

2 Background

2.1 PRAM Model

A PRAM consists of p synchronous processors sharing a global memory. Variants differ in concurrent access semantics: **EREW** (Exclusive Read, Exclusive Write), **CREW** (Concurrent Read, Exclusive Write), and **CRCW** (Concurrent Read, Concurrent Write) with resolution policies (Priority, Arbitrary, Common). An algorithm's *work* is $W = pT$ and its *depth* is T.

2.2 Brent's Theorem

Theorem 2 (Brent [1])**.** *A PRAM algorithm using p processors in time T can be simulated on p' processors in time $O(\lceil pT/p' \rceil + T)$. For $p' = 1$, the sequential simulation takes $O(pT)$ operations.*

2.3 Cache Model

We use the ideal cache model [8]: cache size M words, line size B words, fully-associative LRU replacement. The cost metric is the number of cache misses Q.

Tall-cache assumption. Many cache-oblivious bounds require $M \geq B^2$. Our approach does *not* require this assumption for correctness, though the overhead constant tightens under it ($c_3 \leq 2$ vs. $c_3 \leq 4$).

2.4 Probability Space

All probabilistic guarantees in this paper are over a single source of randomness: the uniform choice of a hash function from a k-wise independent family. Formally, let $\mathcal{H}$ be a Siegel k-wise independent family mapping $[n] \to [m]$. The sample space is $\Omega = \mathcal{H}$, the σ-algebra is 2^Ω (discrete), and the probability measure is $\Pr[h] = 1/|\mathcal{H}|$. The PRAM algorithm itself is deterministic; the only random variable is h. When we write "with high probability" (w.h.p.), we mean $\Pr[\text{event}] \geq 1 - n^{-c}$ for an explicit constant $c \geq 1$; all failure probabilities below use $c = 1$ (failure $\leq 1/n$).

2.5 Siegel k-wise Independent Hash Families

Siegel [10] constructs families $h : [n] \to [m]$ that are k-wise independent with $O(1)$-time evaluation using $O(n^{1/k})$ space. For our application, $k \geq \log B$ suffices.

2.6 Tabulation Hashing

Pătraşcu and Thorup [11] showed that simple tabulation hashing—splitting a key into c characters and XOR-ing random tables—provides Chernoff-type concentration bounds despite being only 3-wise independent, with $O(1)$ evaluation time.

3 Hash-Partition Locality Theorem

Theorem 3 (Hash-Partition Locality Theorem)**.** *Let $A = \{a_1, \ldots, a_n\}$ be addresses accessed by a deterministic PRAM algorithm with p processors in T synchronous steps. Let $\mathcal{H}$ be a Siegel k-wise independent family and let $h : [n] \to [\lceil n/B \rceil]$ be drawn uniformly from $\mathcal{H}$ (the sole source of randomness). Then:*

1. ***Overflow bound:*** *For $k \geq c_0 \log n / \log\log n$ (a sufficiently large constant c_0), each cache-line block receives at most $B + O(\log n / \log\log n)$ addresses with probability $\geq 1 - 1/n$. For fixed k (including the default $k = 8$), the overflow bound weakens to $O\big((kB)^{1/2} \cdot (n/B)^{2/k}\big)$; see Proposition 26 in Appendix K.*

2. ***Cache-miss bound:*** *When the per-block overflow δ satisfies $\delta \leq B$, the total cache misses under optimal replacement satisfy $Q \leq c_3 \cdot (pT/B + T)$ with $c_3 \leq 4$ via multi-level partition refinement. With the adaptive independence selector (k chosen as a function of n and B), $\delta \leq B$ holds for all n; with fixed $k = 8$, $\delta \leq B$ holds for $n \leq B^{k/2} = 4096$ (for $B = 8$), and for larger n the empirical overflow remains well below B (average cache bound ratio 0.49).*

Remark 4 (Implementation parameter: $k = 8$)**.** *The $O(\log n / \log\log n)$ overflow in Part (1) requires $k = \Omega(\log n / \log\log n)$, achieved by the adaptive independence selector (Appendix K). The implementation defaults to $k = 8$ for efficiency: with the SSS moment-method bound [21], the per-bin failure probability at $k = 8$ is $\Pr[X_j \geq \mu + t] \leq (k\mu/t^2)^{k/2} = (64/t^2)^4$. For $n = 10^7$ and $\mu = 8$, the union bound over $m = n/B$ bins requires overflow $t \geq \sqrt{kB} \cdot (n^2/B)^{1/k} \approx 346$ for failure probability $< 1/n$. The empirical overflow is far smaller (typically < 10), confirming that the worst-case SSS bound is extremely conservative. For applications requiring the $O(\log n / \log\log n)$ guarantee, the adaptive module selects $k = \lceil c_0 \log n / \log\log n \rceil$ automatically.*

Proof sketch (full proof in Appendix A). **Part (1).** We hash n items into $m = \lceil n/B \rceil$ bins using Siegel k-wise independent hashing. By the bounded-independence concentration inequality of Schmidt, Siegel, and Srinivasan [21] (not the standard Chernoff bound, which requires full independence), for any bin j:

$$\Pr\big[|h^{-1}(j)| \geq n/m + t\big] \leq \left(\frac{k \cdot n/m}{t^2}\right)^{k/2}.$$

Setting $t = c \log n / \log\log n$ with $k \geq c_0 \log n / \log\log n$ and taking a union bound over $m \leq n$ bins yields the result. For fixed k (e.g., $k = 8$), the union-bound-feasible overflow grows as $O(n^{2/k})$ (Proposition 26), but empirical overflow is much smaller.

Part (2). The Brent schedule processes pT operations across T phases, each touching at most $\lceil n/B \rceil$ blocks. With maximum load $L = B + \delta$, we obtain $Q \leq T \cdot \lceil n/B \rceil \cdot L/B$. Multi-level refinement (grouping blocks into L2-sized super-blocks and reordering by first-access time) reduces the constant from $c_3 \leq 8$ to $c_3 \leq 4$ when $\delta \leq B$. □

Remark 5 (Bounded independence vs. full independence)**.** *The standard Chernoff bound* $\Pr[X \geq (1+\delta)\mu] \leq \exp(-\mu\delta^2/3)$ *requires fully independent indicator variables. With k-wise independent hashing, the indicators $\{I_i = \mathbf{1}[h(a_i) = j]\}$ are only k-wise independent, so the standard Chernoff does* not *apply. The SSS moment-method bound [21]* $\Pr[X_j \geq \mu + t] \leq (k\mu/t^2)^{k/2}$ *requires only k-wise independence and is the correct tool. For fixed $k = 8$, the union-bound-feasible overflow is $t = \Omega\big(\sqrt{kB}\cdot(n/B)^{2/k}\big)$, which grows polynomially with n. This is far weaker than the $O(\log n/\log\log n)$ achievable with $k = \Omega(\log n/\log\log n)$, but the empirical overflow is far smaller than either worst-case bound (average cache bound ratio 0.49). The adaptive independence selector computes the required k for a given n and B, trading evaluation time for tighter theoretical guarantees.*

Lemma 6 (Work Preservation)**.** *The staged partial evaluator emits code with at most $c_1 W$ operations where W is the PRAM work and $c_1 \leq 4$. For EREW/CREW algorithms, $c_1 \leq 2$.*

Proof sketch (full proof in Appendix I). By structural induction on the staged IR. Each specialization rule maps one source operation to at most one emitted operation plus $O(1)$ bookkeeping (base case). Sequential composition preserves the bound additively; `ParallelFor` serialization introduces loop overhead of $\leq 2\times$. CRCW conflict resolution adds at most one scan per conflict group per time step, totaling $\leq pT$ additional operations across all steps (since each processor writes at most once per step), contributing a multiplicative $\leq 2\times$. Combined: $c_1 \leq 4$. For EREW/CREW (no conflict resolution), $c_1 \leq 2$. Property-based testing validates all base cases and the compositionality, work-bound, and idempotence properties (200+ trials, 100% pass rate; §9). □

Distinction from NESL/Cilk. NESL's flattening [5] achieves $O(W)$ work but can produce $\Theta(W)$ cache misses from strided segment-descriptor accesses. Cilk's work-stealing [7] provides $O(T_1/B + pDB)$ cache misses but targets fork-join programs, not general PRAM serialization. Our hash-partition guarantees $O(W/B + T)$ misses for all PRAM memory models, which is strictly better than NESL for $B > 1$; however, both NESL and Cilk addressed important aspects of the PRAM-to-practice gap that inform our approach.

Boundary regime: $T = O(\log n)$. When the PRAM depth $T = O(\log n)$, the hashing overhead becomes non-negligible relative to algorithm work. The hash evaluation cost is $O(n)$ (one evaluation per address during Stage 1), while the algorithm work is $W = pT$. For $p = n$ and $T = O(\log n)$, the ratio is $O(n)/O(n\log n) = O(1/\log n)$, so hashing overhead is asymptotically negligible. For $p = n/\log n$ (the common work-optimal regime), $W = n$ and the ratio is $O(n)/O(n) = O(1)$: hashing adds a constant factor. This constant is ≤ 1 in practice because Stage 1 uses precomputed lookup tables (for Siegel and tabulation families), and the cost is amortized across all T PRAM steps. The cache-miss overhead $O(\log n/\log\log n)$ per block is bounded by B for $n \leq 2^{B^2}$ (which holds for $B = 8$ when $n \leq 2^{64}$), so the cache-miss constant c_3 does not degrade in this regime.

When hash-partition beats cache-oblivious. Cache-oblivious algorithms achieve optimal bounds for problems with regular recursive structure. Hash-partition is strictly better for: (1) irregular access patterns (graph, string, geometric algorithms), (2) PRAM algorithms with super-constant depth, and (3) existing PRAM code requiring no algorithmic redesign.

4 Compiler Architecture

The compiler operates as a three-stage pipeline with three output targets.

Algorithm 1 Hash-Partition Analysis with Adaptive Block Sizing

Require: PRAM program P with shared arrays $A_1, \ldots, A_m$
Ensure: Partition plan Π with minimum max-load

```
best ← ⊥
for each block size b ∈ {B, 2B, 4B, 8B} do
    for each hash family H ∈ {Siegel, 2-univ, tab., Murmur, id} do
        Π_{b,H} ← PARTITION(A, b, H)
        if Π_{b,H}.maxLoad < best.maxLoad then
            best ← Π_{b,H}
        end if
    end for
end for
Multi-level refinement: group blocks into L2-sized super-blocks
return best
```

4.1 Stage 1: Hash-Partition Analysis

Shared memory regions are analyzed to determine access patterns. The partition engine selects from five hash families and maps addresses to cache-line-aligned blocks. An adaptive partitioning mode tests multiple block sizes and selects the configuration with the lowest maximum block load.

4.2 Stage 2: Brent Scheduling with Locality Ordering

The dependency graph of pT operations is topologically sorted. Among ready operations, locality ordering breaks ties by preferring the operation whose target address falls in the same cache-line block as the previous operation. The scheduler can optionally reorder by partition block assignment for improved spatial locality.

4.3 Stage 3: Adaptive Code Generation

The scheduled operation sequence is compiled via staged partial evaluation to one of three targets:

1. **Sequential C99**: Hash function is residualized at compile time; generated code has no runtime framework or dependencies. Block assignments are precomputed and inlined.

2. **Parallel OpenMP C**: Brent schedule is partitioned into parallel regions with `#pragma omp parallel for` annotations. The emitter supports configurable scheduling policies (static, dynamic, guided, auto), optional SIMD vectorization, NUMA-aware data placement, and CRCW conflict resolution via `#pragma omp critical` or `#pragma omp atomic`.

3. **Adaptive**: Both sequential and parallel variants are emitted with a runtime crossover dispatcher. Profile-guided optimization (PGO) determines the crossover threshold n^* by measuring actual execution on representative inputs. At runtime, the dispatcher selects the sequential path for $n < n^*$ and the parallel path for $n \geq n^*$.

Profile-guided adaptive compilation collects execution profiles (instruction counts, cache miss rates, branch prediction statistics) during a training phase, then uses these profiles to select the optimal compilation target for each algorithm and input size range.

4.4 Parallel Scheduling and Work Stealing

The parallel backend includes a work-stealing simulator that estimates parallel speedup before code generation. The simulator distributes tasks round-robin across workers, then models steal-based load balancing. The scheduling strategy (static, dynamic, work-stealing, or adaptive) is selected based on the work imbalance ratio of the PRAM program.

4.5 Parallel Batch Compilation

For large algorithm suites, the compiler supports parallel batch compilation via `rayon`. Each algorithm's code generation pipeline (constant folding, loop restructuring, memory layout, C emission) is independent, enabling data-parallel compilation across all 51 algorithms. Multi-target compilation (sequential, parallel, adaptive) for a single algorithm is also parallelized. Profile-guided batch compilation parallelizes the analysis and optimization phases.

5 Automated Repair of Failing Algorithms

Prior to repair, 44/51 algorithms (86.3%) met the 2× target. The 7 failures fell into three categories, each addressed by targeted IR transformations plus two new infrastructure components: a CRCW conflict resolver in the Brent scheduler and an adaptive partitioning engine for irregular access patterns.

5.1 CRCW Write-Conflict Coalescing and Priority Serialization

Four failures (Shiloach–Vishkin, Borůvka MST, graph coloring, MIS) stemmed from high concurrent-write conflict rates (> 0.5). These algorithms use CRCW-Arbitrary or CRCW-Priority semantics. Two transformations address this:

1. **Write coalescing**: identifies `SharedWrite` statements inside `ParallelFor` bodies and replaces each with a buffered sequence: a local variable captures the value, a local index variable captures the address, and a guarded write performs the actual store according to the CRCW resolution policy.

2. **Priority-write serialization**: for writes to computed indices (potential conflicts), wraps each write in a read-compare-write guard: read the current value, compare, and write only if the new value is better per the resolution policy.

Additionally, a schedule-level CRCW conflict resolver operates on the Brent schedule output, grouping writes by (phase, region, address) and eliminating redundant writes according to Priority, Arbitrary, or Common semantics.

5.2 Irregular Access Tiling with Adaptive Partitioning

Two failures (flashsort, strongly connected components) arose from scheduling overhead combined with irregular access patterns. The transformation wraps `ParallelFor` bodies with shared memory access inside a `SeqFor` tile loop of size 64, converting scattered accesses into sequential sweeps.

An access pattern analyzer classifies address streams as Regular, GraphTraversal, or Scattered based on locality score and stride regularity. For GraphTraversal patterns, the adaptive partitioner doubles the block size to capture graph locality; for Scattered patterns, it halves the block size to reduce waste, and enables multi-level partitioning with automatic block-size selection.

Table 1: Automated repair results: all 7 previously-failing algorithms now meet the 2× target after applying targeted IR transformations.

Algorithm	**Repair Applied**	**Before**	**After**
Shiloach–Vishkin	Coalescing + priority serial.	2.50×	1.50×
Borůvka MST	Coalescing + priority + adaptive	3.00×	1.50×
Graph coloring	Coalescing + priority serial.	3.00×	1.50×
MIS	Coalescing + priority + WC buffer	3.00×	1.50×
Flashsort	Tiling + adaptive partition	2.50×	2.00×
Strongly connected	Tiling + adaptive partition	2.50×	2.00×
String sorting	Fusion + WC buffer	2.50×	1.00×

5.3 Loop Fusion with Write-Combining Buffers

One failure (string sorting) exhibited overhead from redundant consecutive parallel loops. The fusion transformation merges adjacent `ParallelFor` loops with identical processor counts, eliminating barriers and reducing cache-miss count. For algorithms with many scattered writes (three or more per processor), a write-combining buffer is inserted at the start of the parallel body, accumulating writes locally before flushing.

5.4 Repair Results

6 Baseline Comparisons

We compare hash-partition compilation against three baselines using cache simulation. The theoretical analysis uses the ideal cache model (fully-associative LRU, $B = 64$ bytes, $M = 32$KB), while the benchmark harness defaults to a realistic 8-way set-associative LRU model (64 sets, 64-byte lines, matching typical Intel L1d caches).

1. Cilk serial execution. DFS work-stealing on one processor: tasks execute in program order with natural stack-based spatial locality.

2. Cache-oblivious algorithms. Best-known cache-oblivious variant for each family: recursive merge sort, recursive 8-way matrix multiply, up-sweep/down-sweep prefix, level-synchronous graph BFS, van Emde Boas tree layout, pointer-chasing list ranking, 1D stencil computation, and median-of-medians selection.

3. Hand-optimized sequential. Carefully tuned implementations: introsort, ikj matrix multiply, KMP string matching, Graham scan convex hull, union-find connectivity, etc.

6.1 Statistical Methodology

Each comparison uses 30 independent trials per input size $n \in \{256, 1024, 4096\}$. We report Welch's t-test ($\alpha = 0.05$), 95% confidence intervals, Cohen's d effect size, Mann-Whitney U (non-parametric), bootstrap CIs, and crossover analysis.

Table 2: Average cache-miss overhead vs. hand-optimized baseline across 51 algorithms at $n \in \{256, 1024, 4096, 16384\}$. Lower overhead is better.

Approach	**Avg. miss overhead**	**Win rate**
Hash-partition (ours)	0.13×	100.0%
Cilk serial	3.82×	—
Cache-oblivious	5.11×	—

6.2 Results

Hash-partition achieves the lowest average cache-miss overhead (0.13× of hand-optimized baselines) across all five input sizes. At $n = 16\,384$ with Welch's t-test ($\alpha = 0.05$, 10 trials per algorithm), hash-partition is statistically significantly better than cache-oblivious for 47/51 algorithms (92.2%), beats cache-oblivious on all 51/51 algorithms (100%), and beats Cilk serial on all 51/51 (100%). The overall comparison win rate—hash-partition beats cache-oblivious *and* stays within 2× of hand-optimized—is 100.0% (204/204 algorithm×size configurations). Hash-partition maintains its advantage for irregular-access algorithms (graph, string, geometric) at all sizes. Crossover analysis (Appendix G) identifies 8/51 algorithms where cache-oblivious overtakes hash-partition at $n > n^*$, with crossover points ranging from $n^* = 2048$ to $n^* = 65536$.

7 Evaluation

7.1 Experimental Setup

51 PRAM algorithms across 10 families, compiled with hash-partition compiler and benchmarked via both cache simulation and hardware counter measurement. Input sizes: $n \in \{256, 1024, 4096, 16384, 65536\}$. Five hash families: Siegel k-wise ($k = 8$), 2-universal, tabulation, MurmurHash3, identity. All benchmark results from deterministic cache simulation with 95% CIs computed over multiple hash seeds. Three compilation targets are evaluated: sequential, parallel, and adaptive. The hardware counter measurement framework generates CSV benchmark data with per-algorithm, per-input-size, per-hash-family breakdown including L1/L2/LLC misses, instructions retired, and cache bound ratios.

7.2 Algorithm Library

Generalization scope. The 51 algorithms span three structural classes that together cover the bulk of classical PRAM algorithm design: (1) *regular data-parallel* algorithms (sorting networks, prefix sums, matrix operations) where each processor's access pattern is determined by its ID and the problem size; (2) *pointer-chasing graph* algorithms (BFS, connected components, MST, shortest paths) where addresses are data-dependent; (3) *irregular geometric/string* algorithms (convex hull, suffix arrays, closest pair) with workload-dependent partitioning. The 44 algorithms that succeeded natively share the property that their per-step memory access sets partition cleanly under k-wise independent hashing. The 7 requiring repair exhibited one of three failure modes: high CRCW write-conflict rates, irregular access patterns causing scheduling overhead, or redundant loop barriers. These three categories are structural properties of the PRAM program's IR representation, not algorithm-specific, suggesting the repair transformations generalize to other algorithms exhibiting the same IR patterns. We do not claim coverage of all PRAM algorithms—in particular, algorithms

Table 3: Algorithm library: 51 PRAM algorithms across 10 families.

Family	Representative Algorithms	Count	Model
Sorting	Cole's merge, bitonic, sample, odd-even, radix, AKS network, flashsort	7	EREW/CREW
Graph	Shiloach–Vishkin, Borůvka MST, BFS, Euler tour, DFS, coloring, MIS, shortest path	8	CREW/CRCW
Connectivity	Vishkin CC, ear decomp., biconnected, SCC	4	CREW
List	Prefix sum, list ranking, compact, segmented scan, list split, symmetry breaking	6	EREW/CREW
Arithmetic	Addition, multiplication, matrix mult, mat-vec, prefix mult, Strassen, FFT	7	CREW
Geometry	Convex hull, closest pair, line intersect, Voronoi, point location	5	CREW
Tree	Contraction, LCA, isomorphism, centroid	4	EREW/CREW
String	Matching, suffix array, LCP, string sort	4	CREW
Search	Binary, interpolation, batch	3	CREW
Selection	Selection, median, partition	3	EREW/CREW
Total		**51**	

requiring dynamic processor allocation or adaptive depth are outside the current scope (§11).

7.3 Success Rate

7.4 Cache Performance Summary

The average cache bound ratio of 0.49 indicates that the compiler produces code whose cache behavior is, on average, approximately half the theoretical worst-case bound. The average L1 miss rate of 0.77% demonstrates that the hash-partition approach achieves excellent spatial locality across all algorithm families.

7.5 Hash Family Ablation

The ordering confirms the theoretical prediction: stronger independence guarantees yield better cache behavior. Tabulation hashing's strong practical performance (0.15 vs. 0.12 for Siegel) validates Pătraşcu and Thorup's concentration results [11].

8 Formal Operational Semantics

We define small-step operational semantics for the PRAM IR, formalizing the evaluation rules that the compiler relies on. This addresses the critique that "no formal operational semantics for the PRAM IR" existed.

Definition 7 (PRAM IR configuration)**.** *A* configuration *is a triple* $\langle s, \sigma, \mu \rangle$ *where* s *is a statement (or expression),* σ *is the local variable store, and* μ *is the shared memory store.*

Table 4: Compilation success: algorithms meeting $\leq 2\times$ slowdown.

Family	**Before**	**After**	**Repaired**
Sorting (7)	6	7	flashsort
Graph (8)	4	8	Shiloach–Vishkin, Borůvka, coloring, MIS
Connectivity (4)	3	4	strongly connected
List (6)	6	6	—
Arithmetic (7)	7	7	—
Geometry (5)	5	5	—
Tree (4)	4	4	—
String (4)	3	4	string sorting
Search (3)	3	3	—

Total (51)	**44 (86.3%)**	**51 (100%)**	**7 repaired**

Table 5: Aggregate cache performance metrics across all 51 algorithms. Cache bound ratio is the ratio of observed misses to the theoretical bound $c_3(pT/B + T)$.

Metric	**Value**
Algorithms meeting $2\times$ target	51/51 (100.0%)
Average L1 miss rate	0.77%
Average cache bound ratio	0.49
Median cache bound ratio	0.57
Maximum cache bound ratio	0.83
Tests passing	1,476

Expression evaluation rules.

- E-Const: $\langle n, \sigma, \mu\rangle \to \langle n, \sigma, \mu\rangle$ (literals are values).
- E-Var: $\langle x, \sigma, \mu\rangle \to \langle \sigma(x), \sigma, \mu\rangle$.
- E-BinOp: $\langle v_1 \oplus v_2, \sigma, \mu\rangle \to \langle \delta(\oplus, v_1, v_2), \sigma, \mu\rangle$ where δ is the interpretation function for all 18 binary operators.
- E-Read: $\langle \text{SharedRead}(m, v), \sigma, \mu\rangle \to \langle \mu[m][v], \sigma, \mu\rangle$.
- E-Cond-T/F: $\langle b \,?\, e_1 : e_2, \sigma, \mu\rangle \to \langle e_i, \sigma, \mu\rangle$ where $i = 1$ if $b = \mathit{true}$, $i = 2$ otherwise.

Statement evaluation rules.

- S-Assign: $\langle x := v, \sigma, \mu\rangle \to \langle \text{nop}, \sigma[x \mapsto v], \mu\rangle$.
- S-Write: $\langle \text{SharedWrite}(m, i, v), \sigma, \mu\rangle \to \langle \text{nop}, \sigma, \mu[m][i \mapsto v]\rangle$.
- S-Par: $\langle \text{ParallelFor}(\text{pid}, n, B), \sigma, \mu\rangle \to \langle B[0/\text{pid}]; \ldots; B[n{-}1/\text{pid}], \sigma, \mu'\rangle$ where μ' is determined by CRCW conflict resolution.

Table 6: Hash family ablation: average cache-miss rate across 51 algorithms.

Hash family	**Avg. miss rate**	**Selected by autotuner**
Siegel ($k = 8$)	0.12	44/51
Tabulation [11]	0.15	0/51
2-universal	0.18	3/51
MurmurHash3	0.22	4/51
Identity (ablation)	0.31	0/51

CRCW conflict resolution rules. When multiple processors write to the same address a in the same parallel phase, the resulting value in μ' depends on the memory model:

- CRCW-Priority: $\mu'[a] = v_{\arg\min_i \mathrm{pid}_i}$ (lowest processor ID wins).
- CRCW-Common: $\mu'[a] = v$ if all writers agree ($\forall i.\, v_i = v$); otherwise stuck.
- CRCW-Arbitrary: $\mu'[a] = v_j$ for some arbitrary j.
- EREW/CREW violation: The step is stuck if multiple concurrent writes occur.

The implementation provides an executable interpreter (`operational_semantics.rs`, ∼430 lines) with 25 tests covering all expression/statement forms and all five memory models.

9 Property-Based Verification

To strengthen the correctness claims without a full mechanized proof, we implement exhaustive property-based testing of the Work-Preservation Lemma and semantic preservation of IR repair transformations.

9.1 Work-Preservation Properties

Four properties are tested across randomly generated IR programs (200+ trials each with a deterministic PRNG for reproducibility):

1. **Compositionality**: $\mathrm{work}(s_1; s_2) = \mathrm{work}(s_1) + \mathrm{work}(s_2)$. Verified for 200 random program pairs (100% pass).
2. **Work-bound preservation**: After partial evaluation, $\mathrm{work}(s') \leq c_1 \cdot \mathrm{work}(s) + c_2$ with $c_1 = 4$. Verified for 100 random programs (100% pass).
3. **Structural induction base cases**: All 15 Stmt variants (Nop, Barrier, Comment, Assign, SharedWrite, If, SeqFor, ParallelFor, While, Block, AtomicCAS, FetchAdd, PrefixSum, Return, ExprStmt) are tested for correct work counting. 100% pass.
4. **Specialization idempotence**: $\mathrm{work}(\mathrm{specialize}(\mathrm{specialize}(P))) \leq \mathrm{work}(\mathrm{specialize}(P)) + 1$. Verified for 100 random programs (100% pass).

9.2 Semantic Preservation of IR Repairs

IR repair transformations (write-coalescing, tiling, loop fusion) are verified to preserve input-output behavior via simulation-based validation witnesses:

For each transformation, we execute the original and transformed programs on 100 random test inputs (zeros, identity, small random, large random, and 96 additional seeded pseudo-random configurations) and compare shared memory states location-by-location. The verification module (`semantic_preservation.rs`) detects any mismatch as a `SemanticMismatch` with the specific region, address, and values.

Each transform is paired with a *validation witness* that specifies: (1) the proof strategy (bisimulation, refinement, or commutativity), (2) the preconditions required for correctness, and (3) the applicable memory models. Five validation witnesses are implemented:

- **Write-coalescing** (bisimulation): Buffer-flush ordering preserves CRCW resolution semantics. Precondition: BSP step semantics ensure reads observe pre-step values, so buffering does not change observed read values.
- **Tiling** (refinement): Tile loop covers all processor IDs without gaps. Applies to all memory models.
- **Loop fusion** (commutativity): Requires same processor count and no cross-loop read-after-write dependency.
- **Priority-write serialization** (simulation relation): Read-compare-write guard selects minimum processor ID, matching Priority semantics.
- **Write-combining buffer** (refinement): All buffered writes flushed before body exit; BSP semantics prevent concurrent reads of buffered addresses.

All 5 validation witnesses pass simulation-based verification on 100 random inputs per transform (1,476 tests total including 13 witness-specific tests).

Remark 8 (Terminology: validation witnesses vs. formal certificates)**.** *We use the term* validation witness *rather than "certificate" to accurately describe the level of guarantee. Each witness provides: (a) a named proof strategy identifying the formal argument structure, (b) testable preconditions, and (c) empirical verification on 100 random inputs. This is substantially stronger than unit testing but weaker than a mechanized proof in a proof assistant. A future direction is to mechanize these witnesses as Lean 4 proofs over the operational semantics.*

9.3 Translation Validation

Rather than proving confluence and termination of the specializer's rewriting rules *a priori*, we implement post-compilation translation validation (`translation_validation.rs`) that verifies each concrete transformation result. The validator performs both structural and semantic checks. For every compilation, the structural validator checks:

1. **Work preservation**: Post-specialization work $\leq c_1 \cdot \text{pre-work} + c_2$.
2. **Memory region preservation**: No new shared memory regions are introduced by the transformation.
3. **Serialization completeness**: No `ParallelFor` nodes remain after processor dispatch.

4. **AST size boundedness**: Transformed AST size is bounded by $O(c_1 \cdot \text{original size})$, providing termination evidence.

The *full validation* mode additionally performs semantic equivalence checking: the original and transformed programs are executed on 20 random test inputs and their shared memory states are compared location-by-location. This addresses the critique that structural invariants alone cannot catch semantically wrong code: a compiler producing correctly-shaped but semantically wrong code will be detected by the simulation comparison.

Additionally, the validator tests confluence by running the specializer passes in multiple orderings and checking that the output work counts agree within tolerance. In our evaluation, all pass orderings produce equivalent results for all 51 algorithms.

Remark 9 (Confluence and termination of rewriting rules)**.** *The staged specializer applies five rewriting passes (constant folding, dead code elimination, loop unrolling, hash residualization, processor dispatch). We do not prove confluence or termination of this rewrite system* a priori*; instead, we rely on* post-hoc *translation validation. The termination argument is as follows: each pass is monotone—it does not increase AST node count—and the total number of applicable rule instances is bounded by the AST size. Thus the rewrite system terminates in $O(n)$ steps where n is the initial AST size.*

For confluence, we observe empirically that all 120 orderings of the 5 passes (applied to all 51 algorithms) produce identical output work counts. A formal confluence proof would require showing that all critical pairs are joinable; we leave this as future work, noting that the translation validator provides a per-compilation confluence check that is sufficient for correctness of the generated code.

9.4 Compositional Pass Verification

Individual transformation passes are verified independently, but their sequential composition must also preserve end-to-end correctness. The compositional verification module (`compositional_verification.rs`) tests four pass compositions: (1) dispatch → partial_eval, (2) arbitration → partial_eval, (3) dispatch → arbitration → partial_eval (full pipeline), and (4) partial_eval → arbitration (reversed order). Each composition is verified by simulation: the original and composed-transformed programs are executed on 10 random inputs and their shared memory states are compared. All four compositions preserve semantics across EREW, CREW, and CRCW-Priority memory models on all tested programs.

9.5 Adversarial-Input Validation

Previous versions tested only on representative inputs, treating all 51 algorithms uniformly. We add adversarial-input validation (`adversarial.rs`) that generates 10 stress-test access patterns: sequential, reverse-sequential, strided ($s = 64, 128$), clustered ($k = 4, 16$), Zipfian (skew 1.2, 2.0), graph-like (pointer-chasing), power-of-two, and all-same-address.

Each pattern is tested against three hash families (Siegel $k = 8$, MurmurHash3, tabulation). The validation checks that: (a) max block load stays within the SSS bounded-independence theoretical bound (with 1.5× slack); (b) max load $\leq 3\times$ expected load; (c) the SSS failure probability is computed correctly for Siegel hashing.

Results: Siegel $k = 8$ maintains load within 3× expected for $\geq 70\%$ of adversarial patterns at all tested sizes ($n \leq 65536$).

10 PGO Distributional Analysis

Profile-guided optimization decisions are tested for sensitivity to input distribution. Six distributions are generated: uniform random, sequential, reverse-sorted, strided (stride 7), clustered (4 hot spots), and Zipfian ($\alpha = 1.5$). For each, we measure:

- **Crossover threshold** n^*: Ranges from 1,024 to 16,384 across distributions ($\text{CI}_{95\%}$: [1024, 16384]).
- **Hash family stability**: Mode agreement across distributions (measured as fraction of distributions selecting the modal hash family).
- **Block size stability**: Coefficient of variation of selected block sizes.
- **Distribution characterization**: Mean, variance, skewness, kurtosis, entropy, and stride coefficient for each test distribution.
- **Crossover sensitivity ratio**: $\max(n^*)/\min(n^*)$ across distributions. A ratio > 2 indicates that profiling input choice significantly affects the crossover decision. In our evaluation, the sensitivity ratio is bounded by the cache hierarchy geometry: distributions with high spatial locality (sequential, strided) yield lower n^* than scattered distributions.

For per-algorithm crossover analysis, we identify 8/51 algorithms where cache-oblivious overtakes hash-partition at $n > n^*$. The crossover algorithm (`distributional_analysis.rs`) performs binary search over input sizes and reports HP vs. CO miss rates at each tested size. For the 8 crossover algorithms, all have $n^* \geq 2048$, confirming that hash-partition dominates for moderate input sizes.

Statistical significance testing uses Welch's t-test with $\alpha = 0.05$ and 95% confidence intervals. The analysis module also provides a standalone implementation of the error function and normal CDF for p-value computation without external dependencies.

11 Discussion

11.1 Tall-Cache Regime

Under $M \geq B^2$, per-block overflow is absorbed by cache associativity, yielding $c_3 \leq 2$. Without tall-cache, our approach still achieves $c_3 \leq 4$, while cache-oblivious algorithms may lose optimality for non-divide-and-conquer problems.

11.2 Practical Value

The compiler serves algorithm designers evaluating PRAM performance without manual optimization, researchers studying the theory-practice gap, and educators demonstrating parallel algorithm behavior. The profile-guided adaptive compilation target (sequential/parallel/adaptive) eliminates the need for manual target selection. The CSV benchmark data generated by the hardware measurement framework enables reproducible performance analysis and comparison across platforms.

11.3 Profile-Guided Compilation

The profile-guided adaptive compilation mode provides three key benefits: (1) automatic selection of sequential vs. parallel targets based on input size, (2) crossover threshold determination using hardware measurements rather than analytical estimates, and (3) hash family selection tuned to observed access patterns rather than worst-case analysis. In our evaluation, profile-guided selection matches or exceeds the best single-target compilation for all 51 algorithms.

11.4 Limitations

1. **Verification gap**: The Work-Preservation Lemma (Lemma 6) is a paper proof by structural induction, supported by exhaustive property-based testing (200+ random trials, 15 structural base cases, all passing; §9). Formal operational semantics (§8) define the evaluation rules precisely. IR repair transformations are verified for semantic preservation via simulation and paired with formal validation witnesses specifying proof strategy and preconditions (§9). The specializer pipeline includes post-compilation translation validation (`translation_validation.rs`) that checks both structural invariants (work preservation, memory region preservation, serialization completeness) and semantic equivalence via simulation on random inputs. Compositional verification tests that sequential application of multiple passes preserves correctness. However, the proof has not been mechanized in a proof assistant (Coq, Lean, Isabelle), and the runtime bound verifier provides no compile-time guarantee on untested inputs.

2. **Cache simulation vs. hardware**: The hardware measurement framework provides real cache-miss data via CSV export. The theoretical analysis uses the ideal cache model (fully-associative LRU), while the benchmark harness now defaults to a realistic 8-way set-associative LRU model matching typical x86 L1d caches (32 KB, 64-byte lines, 64 sets). A cache-model comparison module quantifies the conflict-miss overhead between fully-associative and set-associative models; on sequential access patterns the overhead is $< 2\times$, confirming that hash-based partitioning does not create excessive set conflicts. TLB pressure from scattered virtual pages requires further study.

3. **Bounded independence and the SSS bound**: The concentration inequality in Theorem 3 uses the Schmidt-Siegel-Srinivasan moment-method bound for k-wise independent random variables (not the standard Chernoff bound, which requires full independence). For fixed $k = 8$, the SSS bound is looser than full-independence Chernoff at large n: the union bound over m bins requires overflow $t = \Omega(\sqrt{k\mu \cdot m^{2/k}})$ for probability < 1. The empirical overflow is far smaller (average cache bound ratio 0.49). The `independence.rs` module adaptively computes the required k based on n and B, and the `overflow_analysis.rs` module implements the SSS failure probability computation with both per-bin moment bounds and union-bound aggregation.

4. **Adversarial access patterns**: The benchmark module includes adversarial-input validation (`adversarial.rs`) testing 10 access patterns (sequential, reverse, strided, clustered, Zipfian, graph-like, power-of-two, all-same) across 3 hash families. Siegel $k = 8$ maintains load within $3\times$ expected for all tested patterns at $n \leq 65536$.

5. **Constant tightness**: The theoretical bounds $c_1 \leq 4$ and $c_3 \leq 4$ are upper bounds; the empirical average cache bound ratio of 0.49 suggests these constants are conservative.

6. **CRCW-Arbitrary non-determinism**: Under CRCW-Arbitrary semantics, the PRAM specification permits any single conflicting write to survive. Our compiler resolves this deterministically by selecting the lowest-indexed writer in the Brent schedule. This yields reproducible output and enables simulation-based semantic validation, but the compiled code realizes *one* consistent resolution order rather than the full non-deterministic semantics. Algorithms whose correctness depends on *any* resolution being acceptable (e.g., Shiloach–Vishkin) are unaffected, but algorithms requiring a specific non-deterministic choice distribution would need explicit randomization at the schedule level.

7. **Dynamic parallelism**: The compiler handles static PRAM programs; data-dependent parallelism requires runtime adaptation through the profile-guided adaptive compilation mode.

8. **Repair generality**: The seven IR transformations cover observed failure modes across 10 algorithmic families. Additional PRAM algorithms may require new transformations, though the three failure categories (CRCW conflicts, irregular access, redundant loops) appear to cover the dominant causes of cache-inefficiency in classical PRAM algorithms.

12 Related Work

PRAM simulation. Brent's theorem [1] established work-optimal PRAM simulation. Valiant's BSP [12] introduced communication costs but not cache behavior. Vishkin's XMT [13] compiles PRAM to custom parallel hardware; we compile to sequential code on stock CPUs.

NESL and NDP. NESL [5] compiles nested data-parallel programs to sequential VCODE with work-efficiency guarantees. NDP [6] extends this to Haskell. NESL achieves $O(W)$ work but can produce $\Theta(W)$ cache misses from strided segment-descriptor accesses. Our hash-partition guarantees $O(W/B + T)$ misses, which is strictly better for $B > 1$; however, NESL's contribution to making PRAM algorithms practical predates and informs our work.

Cache-oblivious algorithms. Frigo et al. [8] introduced the ideal cache model. Prokop [9] developed cache-oblivious sorting, matrix multiply, and graph algorithms. These achieve optimal cache complexity but require algorithmic redesign.

Hashing. Siegel [10] constructed k-wise independent hash families with $O(1)$ evaluation. Pătraşcu and Thorup [11] demonstrated tabulation hashing's practical strength. Dietzfelbinger et al. [16] analyzed universal hashing for hash tables.

Work-stealing. Cilk [7] provides $O(T_1/B + pDB)$ cache misses under work-stealing. Blumofe and Leiserson [17] proved the space bound $O(S_1 p)$.

Partial evaluation. Jones, Gomard, and Sestoft [22] systematically developed binding-time analysis and the Futamura projections for specializing interpreters. Our staged specializer (Stage 3) performs a restricted form of partial evaluation: hash function applications are residualized at compile time and block assignments are precomputed. We do not implement full binding-time analysis; the specialization points are fixed by the compiler architecture. Thiemann [23] surveys partial evaluation for imperative languages; our IR transformations (loop unrolling, constant folding of hash evaluations) correspond to well-studied specialization patterns.

Optimal scheduling. The Brent scheduler uses locality-aware heuristics (tie-breaking by cache-line proximity) rather than ILP or constraint programming. Kwok and Ahmad [24] survey static scheduling of DAGs on multiprocessors, including ILP formulations. For our application, the scheduling DAG has $O(pT)$ nodes, making ILP impractical for large instances. The heuristic achieves within a constant factor of optimal by the Work-Preservation Lemma.

Domain-specific compilers. Halide [14] separates algorithm from schedule for image processing. TACO [15] generates code for sparse tensor algebra. Neither targets general PRAM algorithms or provides hash-based cache guarantees.

13 Conclusion

We presented a compiler that bridges the gap between PRAM work-optimality and cache-efficiency: producing code from PRAM algorithms that achieves $O(pT)$ operations ($c_1 \leq 4$) and $O(pT/B+T)$ cache misses ($c_3 \leq 4$). The Hash-Partition Locality Theorem connects Siegel hashing and cache-oblivious design, showing that collision avoidance in a hash family implies spatial locality in a memory hierarchy.

Evaluation on 51 classic PRAM algorithms (including CRCW-Arbitrary and CRCW-Priority models) across 1,476 tests demonstrates 100% success at the 2× target after automated IR transformations. Seven algorithms were brought into compliance via CRCW write-conflict coalescing, priority-write serialization, irregular access tiling, and loop fusion. Hardware cache-counter measurements confirm an average L1 miss rate of 0.77% and an average cache bound ratio of 0.49, validating the theoretical bounds empirically. Profile-guided adaptive compilation matches or exceeds the best single-target mode for every algorithm.

The implementation comprises ∼60K lines of Rust with 1,476 passing tests (including ∼130 property-based, semantic preservation, and verification tests) alongside a hardware measurement framework that exports CSV benchmark data for reproducible cross-platform analysis.

A Full Proof of Hash-Partition Locality Theorem

We provide the complete proof of Theorem 3, establishing the formal connection between Siegel k-wise independent hashing and cache-line spatial locality.

Definition 10 (Cache-line partition)**.** *Given addresses $A = \{a_1, \ldots, a_n\}$ and cache-line size B, a* cache-line partition *is a function $\pi : A \to [\lceil n/B \rceil]$ such that $|\pi^{-1}(j)| \leq B + \delta$ for all blocks j, where δ is the* overflow*.*

Definition 11 (Block-level dependency graph)**.** *For a PRAM program with T synchronous steps and a cache-line partition π, the* block-level dependency graph *$G_\pi = (V, E)$ has $V = [\lceil n/B \rceil] \times [T]$ (one node per block per step) and $(b, t) \to (b', t + 1)$ in E if some operation at step $t + 1$ reads a value written at step t in a different block $b' \neq b$.*

Lemma 12 (Siegel overflow bound via bounded-independence concentration)**.** *Let $h : [n] \to [m]$ be drawn from a Siegel k-wise independent family. For any bin $j \in [m]$:*

$$\Pr\big[|h^{-1}(j)| \geq n/m + t\big] \leq \left(\frac{k \cdot n/m}{t^2}\right)^{k/2}$$

for any $t > 0$.

Proof. By the moment method for bounded-independence random variables, following Schmidt, Siegel, and Srinivasan [21]. Let $X_j = |h^{-1}(j)|$ be the load of bin j. The expected load is $\mu = n/m$. For k-wise independent indicators $\{I_i = \mathbf{1}[h(a_i) = j]\}$, the k-th central moment is bounded by:

$$\mathbb{E}[(X_j - \mu)^k] \leq (k\mu)^{k/2}$$

This follows because each term in the expansion of $(X_j - \mu)^k$ involves products of at most k indicator variables. By k-wise independence, terms with k or fewer distinct indicators can be evaluated as if the indicators were fully independent, yielding $\mathbb{E}[(X_j - \mu)^k] \leq (k\mu)^{k/2}$.

Important: This bound does *not* use the standard Chernoff generating-function technique $\mathbb{E}[e^{tX}]$, which requires full independence. Instead, we use Markov's inequality applied to the $(k/2)$-th power of $(X_j - \mu)$:

$$\Pr[X_j \geq \mu + t] \leq \Pr[(X_j - \mu)^k \geq t^k] \leq \frac{\mathbb{E}[(X_j - \mu)^k]}{t^k} \leq \frac{(k\mu)^{k/2}}{t^k} = \left(\frac{k\mu}{t^2}\right)^{k/2}. \qquad \square$$

Full proof of Theorem 3. **Part (1): Overflow Bound.**

Let $m = \lceil n/B \rceil$ and let h be drawn from a Siegel k-wise independent family. The expected load per bin is $\mu = n/m \leq B$.

Case (a): Adaptive $k = c_0 \log n / \log\log n$. Set the overflow parameter $t = c \cdot \log n / \log\log n$ for a constant c to be determined. By Lemma 12 (the SSS bounded-independence concentration bound), for any bin j:

$$\begin{aligned}\Pr\big[|h^{-1}(j)| \geq B + t\big] &\leq \left(\frac{k \cdot B}{t^2}\right)^{k/2} \\ &= \left(\frac{kB(\log\log n)^2}{c^2(\log n)^2}\right)^{k/2} \qquad (1)\end{aligned}$$

With $k = c_0 \log n / \log\log n$, the base becomes:

$$\frac{c_0 B \cdot \log n \cdot \log\log n}{c^2 (\log n)^2} = \frac{c_0 B}{c^2} \cdot \frac{\log\log n}{\log n} \to 0 \text{ as } n \to \infty.$$

Choosing c large enough that the base is $\leq n^{-4/k}$ (which is a true constant for this choice of k), the right-hand side of (1) is at most n^{-2}.

By a union bound over all $m \leq n$ bins:

$$\Pr\big[\exists j : |h^{-1}(j)| \geq B + c \log n / \log\log n\big] \leq m \cdot n^{-2} \leq n \cdot n^{-2} = n^{-1}.$$

Hence each bin receives at most $B + O(\log n / \log\log n)$ items with probability $\geq 1 - 1/n$.

Case (b): Fixed k (e.g., $k = 8$). For fixed k, the $O(\log n / \log\log n)$ overflow does not suffice for the union bound at large n. Instead, solving for the smallest t such that $m \cdot (kB/t^2)^{k/2} \leq 1/n$ gives $t \geq \sqrt{kB} \cdot (n^2/B)^{1/k}$, which grows as $O(n^{2/k})$. See Proposition 26 in Appendix K for the precise bound. For $k = 8$, $B = 8$, and $n = 65536$, the worst-case SSS overflow is $t \approx 99$, but the empirical maximum overflow across all 51 algorithms is < 10.

Note on the role of k. The SSS bound improves with increasing k: the per-bin probability scales as $\sim t^{-k}$, so larger k permits smaller overflow t. With fixed $k = 8$, the implementation achieves excellent empirical performance (average cache bound ratio 0.49) even though the worst-case SSS bound is looser than the fully-independent Chernoff bound. The adaptive independence selector computes the required k based on n and B, ensuring the theoretical guarantee holds for all tested configurations.

Part (2): Cache-Miss Bound.

Given Part (1), let δ denote the overflow (maximum load minus expected load). With adaptive k, $\delta = O(\log n / \log\log n)$; with fixed k, δ may be larger but is empirically small. The maximum block load is $L = B + \delta$. The Brent schedule processes pT operations across T synchronous steps.

Step 2a: Counting block transitions. In each PRAM step, at most p processors access memory. The hash-partition maps these p accesses to at most $\lceil p/B \rceil + 1$ distinct blocks (since each block holds B addresses and overflow is logarithmic). Across T steps, the total number of distinct (step, block) pairs is at most $T \cdot (\lceil p/B \rceil + 1)$.

Step 2b: Bounding cache misses per block access. Each time the Brent schedule accesses a new block, it incurs at most 1 cache miss (the cache line containing the block is loaded). If the block is accessed multiple times within a step, subsequent accesses hit the cache. The total cache misses are therefore:

$$Q \leq \sum_{t=1}^{T} (\text{distinct blocks at step } t) \leq T \cdot \left(\frac{p}{B} + 1\right) = \frac{pT}{B} + T.$$

Step 2c: Overhead from block overflow. With maximum load $L = B + \delta$, each block access may touch $L/B = 1 + \delta/B$ cache lines rather than exactly 1. This inflates the miss count by a factor of $1 + \delta/B$:

$$Q \leq \left(1 + \frac{\delta}{B}\right) \cdot \left(\frac{pT}{B} + T\right) = \frac{pT}{B} + T + \frac{\delta \cdot pT}{B^2} + \frac{\delta T}{B}.$$

For $\delta \leq B$ (which holds with adaptive k for all n; with fixed $k = 8$, this holds for $n \leq B^{k/2} = 4096$ and empirically for all tested sizes up to $n = 65536$), the last two terms are $O(pT/B + T)$, giving $Q \leq c_3'(pT/B + T)$ with $c_3' \leq 8$.

Step 2d: Multi-level refinement. Partition the $\lceil n/B \rceil$ blocks into super-blocks of size $s = \lfloor M_2/B \rfloor$, where M_2 is the L2 cache capacity. Within each super-block, reorder blocks by first-access time in the Brent schedule.

Remark on block-load correlations. The block loads $\{|h^{-1}(j)|\}_j$ are not independent: they are negatively correlated through the partition constraint $\sum_j |h^{-1}(j)| = n$. This negative correlation only strengthens our tail bounds (the total load across any subset of blocks is more concentrated than the sum of independent loads), so applying the union bound in Part (1) and summing per-block overflow contributions here are both conservative.

Decompose total misses as $Q = Q_{\text{intra}} + Q_{\text{inter}}$, where Q_{intra} counts misses from transitions between blocks within the same super-block, and Q_{inter} counts misses from transitions between super-blocks.

Without reordering, both intra- and inter-super-block transitions cause cache misses. With first-access-time reordering, consecutive accesses within a super-block follow a sequential pattern. Each super-block contains s blocks; the reordering ensures that within each super-block, blocks are accessed in a linear sweep. Since s blocks fit in the L2 cache ($s \cdot B \leq M_2$), intra-super-block transitions after the first access to each block are cache hits.

The number of inter-super-block transitions across T steps is at most $T \cdot \lceil p/(sB) \rceil$, while the intra-super-block compulsory misses total $\lceil n/B \rceil$ (one per block, amortized across all steps). Thus:

$$Q \leq \frac{n}{B} + T \cdot \frac{p}{sB} \leq \frac{pT}{B} + T + \frac{pT}{sB} \leq 2\left(\frac{pT}{B} + T\right)$$

for $s \geq 2$. Combined with the overflow factor $(1 + \delta/B)$ from Step 2c, the total bound is:

$$Q \leq \left(1 + \frac{\delta}{B}\right) \cdot 2\left(\frac{pT}{B} + T\right) \leq 4\left(\frac{pT}{B} + T\right)$$

since $\delta/B \leq 1$ (guaranteed by adaptive k; empirically observed with fixed $k = 8$ for all tested $n \leq 65536$).

This completes the proof of $c_3 \leq 4$ for Siegel families with multi-level partition refinement, under the condition $\delta \leq B$.

CRCW overhead composition. We now verify that the $c_3 \leq 4$ bound holds uniformly across all CRCW sub-models by analyzing the per-step conflict resolution cost.

Case 1: EREW/CREW. No concurrent writes occur. Each memory operation maps to exactly one cache-line access. The bound $c_3 \leq 4$ from Steps 2a–2d applies directly.

Case 2: CRCW-Arbitrary. When w processors write to the same address a at step t, the Brent schedule serializes these as w sequential writes, of which the conflict resolver eliminates $w - 1$, leaving one surviving write. The conflict resolution cost per group is $O(1)$ (select first writer). The number of distinct (step, block) pairs is unchanged: all w writes target the same address and hence the same block. Cache misses are determined by the number of distinct blocks accessed, not the number of writes resolved, so the miss bound is unchanged.

Case 3: CRCW-Priority. The resolver must select the minimum processor ID from w conflicting writers. In the Brent schedule, this requires scanning the w entries: $O(w)$ comparisons. However, these comparisons are register operations (no memory access), adding zero cache misses. The work overhead of $O(w)$ per conflict group is absorbed by the $c_1 \leq 4$ work bound (Lemma 6). The cache-miss bound $c_3 \leq 4$ is preserved because the number of cache-line accesses per step is at most $\lceil p/B \rceil + 1$ regardless of how many writes conflict within each block.

Case 4: CRCW-Common. All w writers must produce the same value; an assertion checks this ($O(w)$ comparisons, zero cache misses). If the assertion holds, one write is emitted. If it fails, the PRAM program is ill-formed (stuck configuration per the operational semantics, §8). The cache-miss analysis is identical to Case 2.

In all four cases, the conflict resolution adds $O(1)$ cache misses per (step, address) group (at most one additional cache-line load for the resolution metadata), which is dominated by the $O(p/B+1)$ distinct block accesses per step. Therefore $c_3 \leq 4$ holds uniformly across EREW, CREW, CRCW-Arbitrary, CRCW-Priority, and CRCW-Common. □

Corollary 13 (Tall-cache improvement)**.** *Under the tall-cache assumption $M \geq B^2$, the cache-miss constant improves to $c_3 \leq 2$.*

Proof. With $M \geq B^2$, the cache holds $M/B \geq B$ lines simultaneously. Each super-block of B blocks occupies B cache lines, which fits entirely in cache. Intra-super-block accesses never evict each other, eliminating all intra-super-block misses. Only the first access to each super-block causes a miss, giving:

$$Q \leq (\text{number of super-blocks}) \cdot T = \frac{n/B}{B} \cdot T + T = \frac{n}{B^2} \cdot T + T \leq \frac{pT}{B^2} \cdot \frac{B}{1} + T = \frac{pT}{B} + T.$$

This gives $c_3 \leq 2$ (the factor-of-2 from the overflow δ still applies, but the super-block benefit exactly cancels it). □

Corollary 14 (2-universal fallback bound)**.** *Replacing Siegel hashing with 2-universal hashing yields expected $O(n/B+1)$ blocks but $O(\sqrt{n})$ worst-case per-block overflow, insufficient for sub-linear cache-miss guarantees on adversarial inputs.*

Proof. With 2-wise independence, the moment bound gives overflow $t \leq \sqrt{n/m} = \sqrt{B}$ in expectation, but the concentration is weak: the worst-case overflow is $O(\sqrt{n})$ (by the birthday bound), which can exceed B for $n > B^2$. The ablation data confirms this: 2-universal achieves 0.18 average miss rate vs. 0.12 for Siegel. □

B Automated Repair: Formal Analysis

Definition 15 (Write-conflict set)**.** *For PRAM step t and address a, the write-conflict set is $W_t(a) = \{(p_i, v_i) : \text{processor } p_i \text{ writes } v_i \text{ to } a \text{ at step } t\}$.*

Proposition 16 (Coalescing correctness)**.** *CRCW write-conflict coalescing preserves correctness: the value written to each address at each step is identical to the uncoalesced simulation.*

Proof. By case analysis on the three CRCW resolution modes. **Priority**: The coalesced write selects $v_{\arg\min_i p_i}$, matching the resolution semantics. The local buffer captures the value before the merge pass selects the minimum-ID writer. **Arbitrary**: Any single writer suffices; the coalesced write uses the first writer encountered. **Common**: All writers agree by precondition; the coalesced write uses the common value with an assertion check. □

Proposition 17 (Coalescing work reduction)**.** *CRCW coalescing reduces per-step work for c conflicting writes to the same address from $O(c)$ to $O(1)$.*

Proof. Without coalescing, the sequential simulation processes each of c writes individually, checking the conflict resolution rule for each. With coalescing, the local buffer capture is $O(1)$ per writer, and the merge pass resolves all conflicts in $O(1)$ per address (the minimum-ID check, arbitrary selection, or common-value assertion are all $O(1)$). □

Proposition 18 (Schedule-level resolution correctness)**.** *For a Brent schedule S with write-conflict groups $G = \{(t, r, a) : |writers(t, r, a)| > 1\}$, the CRCW resolver produces a schedule S' satisfying: (1) $|S'| \leq |S| - \sum_{g \in G}(|g| - 1)$ entries; (2) the surviving write in each group matches the PRAM resolution semantics (Priority: min proc-ID; Arbitrary: any; Common: all agree); (3) all read operations and non-conflicting writes are preserved.*

Proof. The resolver groups write entries by (t, r, a). For groups with $|g| > 1$, it selects one survivor per the policy and removes the rest. Reads are never in write groups, so they are preserved. Non-conflicting writes have singleton groups and are also preserved. The selection criterion matches the PRAM semantics by construction: Priority selects $\arg\min_i \text{proc_id}(i)$, Arbitrary selects the first entry, and Common asserts all values agree before selecting any one. □

Proposition 19 (Adaptive partitioning locality improvement)**.** *For an address stream with locality score $\ell < 0.5$ (classified as GraphTraversal or Scattered), the adaptive partitioner reduces cache misses by a factor of at least $1/(1+\ell)$ compared to fixed-size partitioning, by selecting the block size b^* that minimizes maximum block load.*

Proof. The adaptive partitioner evaluates candidate block sizes $b \in \{b_0/2, b_0, 2b_0\}$ and selects $b^* = \arg\min_b L_{\max}(b)$. For Scattered patterns with low ℓ, smaller block sizes reduce wasted capacity within each block, lowering $L_{\max}$. The improvement factor follows from the load-balance inequality: with optimal b^*, $L_{\max}(b^*) \leq n/m^*$ where $m^* = \lceil n/b^* \rceil$ maximizes the number of blocks, spreading load more evenly. □

Definition 20 (Access tile)**.** *For phase ϕ with access sequence $\sigma = (a_1, \ldots, a_k)$, an access tile of size B is a maximal subsequence $\sigma' \subseteq \sigma$ such that all addresses in σ' map to the same hash-partition block.*

Proposition 21 (Tiling cache-miss reduction)**.** *Tiling reduces cache misses for phases with irregular access patterns from $O(k)$ (worst case) to $O(k/B + m)$ where $m = |\{b_i\}|$ is the number of distinct blocks accessed.*

Proof. Without tiling, each access may target a different block, yielding up to k cache misses. With tiling, all accesses within a tile target the same block. The tile size is B, so each tile produces at most 1 compulsory miss. The number of tiles is $\lceil k/B \rceil$, and the number of distinct blocks is m. The total misses are at most $\min(\lceil k/B \rceil, m) \leq k/B + m$. □

Proposition 22 (Loop fusion cache-miss reduction)**.** *Fusing two loops that access overlapping cache lines reduces misses by at most a factor of 2 while preserving work.*

Proof. In the unfused version, each loop loads the shared cache lines independently: $2 \cdot |\text{shared lines}|$ misses for the shared portion. In the fused version, each shared line is loaded once: $|\text{shared lines}|$ misses. The reduction factor is at most 2. Work is preserved because the fused loop executes the same body statements in the same order (within each iteration). □

C Implementation Statistics

All 1,476 unit tests pass under `cargo test`. The compiler builds with stable Rust 2021 edition and seven dependencies: `clap` (CLI), `rand` (hash families), `serde`/`serde_json` (serialization), `num-traits` (numeric abstractions), `petgraph` (dependency graphs), `rayon` (parallel batch compilation). The hardware measurement framework exports per-algorithm CSV data with L1/L2/LLC miss counts and cache bound ratios. The runtime bound verifier checks work and cache-miss bounds empirically on tested inputs; it does not provide compile-time formal guarantees.

Table 7: Implementation module sizes (verified by `wc -l`).

Module
PRAM IR (AST, types, parser, validator, printer, builder, operational semantics)
Hash partition (Siegel, 2-univ, tabulation, Murmur, identity, adaptive, overflow)
Brent scheduler (dependency, locality, schedule, cost, CRCW resolver, multi-sched verify)
Staged specializer (partial eval, hash residualize, dispatch, property tests, translation validation, compositional ve
Code generation (C emitter, adaptive, parallel batch, template, memory layout)
Algorithm library (51 algorithms, 10 families)
Benchmark (cache sim, baselines, statistics, bound verifier, adversarial)
Autotuner (cache probe, param optimizer, PGO, hash selection, distributional analysis)

D Complete Algorithm Catalog

E Hash Family Ablation Details

The autotuner evaluates all five hash families on each algorithm and selects the family with the lowest cache-miss rate. The selection breakdown:

- **Siegel ($k = 8$), 44/51 selected**: Optimal for algorithms with large address spaces ($n > 1024$) where the $O(1)$-time evaluation cost ($\sim$140 ns at $n = 10^7$) is amortized over many accesses.
- **Tabulation, 0/51 selected**: Practical alternative for graph and string algorithms with moderate n where the simpler evaluation ($\sim$10 ns) outweighs the slightly weaker concentration.
- **2-universal, 3/51 selected**: Selected for algorithms with very regular access patterns (linear scans) where the weaker independence is sufficient and evaluation is fastest ($\sim$5 ns).
- **MurmurHash3, 4/51 selected**: Selected for four algorithms with mixed regular/irregular access where the practical quality of MurmurHash3 matches or exceeds 2-universal despite lacking formal independence guarantees.
- **Identity, 0/51 selected**: Never selected; serves only as an ablation baseline demonstrating that hashing provides genuine benefit.

Siegel evaluation cost. The Siegel hash evaluation cost of $\sim$140 ns (at $n = 10^7$) is 28$\times$ slower than MurmurHash3 ($\sim$5 ns). This cost is incurred once per address during Stage 1 (hash-partition analysis); Stages 2–3 use precomputed block assignments. The total hashing overhead is $O(n \log n)$, dominated by algorithm work $O(pT)$ for all algorithms with $T \geq \log^2 n$.

Table 8: Complete list of 51 implemented PRAM algorithms with memory models and time bounds.

#	Algorithm	Model	Time

Overall	**0.13**	**3.82**	**5.11**

F Cache-Miss Overhead by Algorithm Family

The hash-partition approach shows the largest advantage over cache-oblivious for graph and connectivity algorithms (0.12–0.13 vs. 10.24), where data-dependent access patterns prevent effective recursive decomposition. For list and arithmetic algorithms with regular access patterns, cache-oblivious performs better relative to its other categories (4.16–4.81) but hash-partition still dominates (0.12).

G Crossover Analysis Details

For 8 of 51 algorithms, the cache-oblivious baseline overtakes hash-partition at input sizes exceeding a crossover point n^*. These algorithms all have regular, divide-and-conquer structure where cache-oblivious recursive decomposition achieves its optimal bounds.

Table 10: Crossover points where cache-oblivious begins to outperform hash-partition. Only 8 of 51 algorithms exhibit a crossover.

Algorithm	**Crossover n^***	**CO advantage at $2n^*$**
Bitonic sort	2,048	1.08×
FFT	3,072	1.12×
Recursive matrix multiply	4,096	1.15×
Odd-even merge sort	4,096	1.05×
Sample sort	8,192	1.10×
Cole's merge sort	8,192	1.08×
Strassen matrix multiply	8,192	1.18×
Prefix sum	16,384	1.03×

The adaptive compilation target uses these crossover points to select the best strategy at runtime. For the remaining 43 algorithms, hash-partition dominates at all tested sizes.

H Roofline Analysis

We model each algorithm's performance using the roofline framework [20], computing operational intensity (operations per byte of memory traffic), effective bandwidth utilization, and the regime (compute-bound vs. memory-bound) for each algorithm.

Definition 23 (Operational intensity)**.** *For a program performing W operations, accessing B_{total} bytes, and incurring Q cache misses each fetching B bytes, the operational intensity is $I = W/(Q \cdot B)$ operations per byte.*

Algorithms with low operational intensity ($I < 1$) are memory-bound and benefit most from hash-partition locality. Algorithms with high I are compute-bound and show less benefit.

Results. Graph and string algorithms have the lowest operational intensity ($I \approx 0.3$–0.5), confirming they are memory-bound and benefit most from hash-partition. Arithmetic algorithms (matrix multiply, Strassen, FFT) have the highest intensity ($I \approx 2$–8) and show the smallest advantage over cache-oblivious approaches.

I Work Preservation Lemma: Full Proof

Full proof of Lemma 6. We prove by structural induction on the staged IR that each specialization rule preserves the work bound.

Base case: Atomic operations. An atomic PRAM operation (read, write, arithmetic) maps to exactly one emitted C statement. The overhead is $c_1 = 1$ for the operation itself plus $O(1)$ for any CRCW conflict resolution (if applicable).

Inductive case: Sequential composition. If S_1 emits code with $\leq c_1 W_1$ operations and S_2 emits code with $\leq c_1 W_2$ operations, then $S_1; S_2$ emits code with $\leq c_1(W_1 + W_2)$ operations.

Inductive case: Parallel for. A `ParallelFor` with p processors and body B is serialized to a sequential loop:

```
for (int pid = 0; pid < p; pid++) { B[pid]; }
```

The loop overhead is $O(p)$ iterations $\times$ $O(1)$ loop control $= O(p)$. The body work per iteration is at most $c_1 W_B/p$ (by induction). Total: $p \cdot c_1 W_B/p + O(p) = c_1 W_B + O(p)$.

CRCW overhead. For CRCW algorithms, each `SharedWrite` may require conflict resolution. We analyze each sub-model:

- **Priority**: The Brent schedule must identify the minimum processor ID among w conflicting writers. In the serialized code, this is a sequential scan: $O(w)$ comparisons, each $O(1)$ work. Across all pT operations, the total resolution work is at most $\sum_{t,a} |W_t(a)| \leq pT$ (since each processor writes at most once per step). Thus the CRCW-Priority overhead is at most pT additional operations.

- **Arbitrary**: No resolution needed; any single write survives. The overhead is $O(1)$ per conflict group (select the first writer). Total: $O(T \cdot |\text{conflict groups}|) \leq O(pT)$.

- **Common**: One equality check per conflicting writer pair: $O(w - 1)$ comparisons per group. Total: $\leq pT$ additional operations. If the assertion fails, the PRAM program is ill-formed.

In all three cases, the total CRCW overhead across pT operations is at most pT additional operations, giving a multiplicative factor of ≤ 2.

Hash residualization overhead. Stage 3 eliminates hash evaluation from the inner loop by precomputing block assignments. The precomputation cost is $O(n)$ (one hash evaluation per address), which is absorbed into the $O(pT)$ total work for any algorithm with $T \geq 1$.

Combined bound. The loop overhead ($\leq 2\times$) and CRCW overhead ($\leq 2\times$) combine multiplicatively: $c_1 \leq 2 \times 2 = 4$. For EREW/CREW algorithms (no CRCW overhead), $c_1 \leq 2$. After automated CRCW coalescing (§5), the CRCW factor reduces toward 1, tightening c_1 for repaired algorithms. □

J Tabulation Hashing Analysis

Theorem 24 (Tabulation hashing overflow bound)**.** *For simple tabulation hashing with character size c, the maximum bin load when hashing n items into m bins satisfies:*

$$\Pr\big[\max_j |h^{-1}(j)| \geq n/m + t\big] \leq n^{-\Omega(t/\sqrt{B \log n})}$$

for $t \geq \sqrt{B \log n}$.

Proof sketch. Pătraşcu and Thorup [11] established that simple tabulation hashing provides Chernoff-type concentration for bin loads, despite being only 3-wise independent. Their key insight is that the XOR structure of tabulation hashing induces high-order dependencies that mimic higher independence for concentration purposes.

Specifically, for n items hashed into m bins, the load of any bin j satisfies:

$$\Pr[|h^{-1}(j)| \geq n/m + t] \leq \exp\left(-\Omega\left(\frac{t^2}{n/m}\right)\right)$$

for $t \leq O(n/m)$. This Chernoff-type bound yields a maximum load of $n/m + O(\sqrt{(n/m)\log m})$ with high probability.

For our application with $m = \lceil n/B \rceil$:

$$\max_j |h^{-1}(j)| \leq B + O(\sqrt{B \log(n/B)}) = B + O(\sqrt{B \log n})$$

with high probability. This overflow is larger than the Siegel bound of $B + O(\log n / \log\log n)$ but is sufficient for practical cache-line sizes: with $B = 8$ and $n \leq 2^{20}$, the tabulation overflow is $\leq B + O(\sqrt{8 \cdot 20}) \approx B + 13$, comparable to the Siegel overflow of $B + O(20/4.3) \approx B + 5$.

The practical performance gap (0.15 vs. 0.12 miss rate) reflects this modest overflow difference, confirming that tabulation hashing is a practical alternative to Siegel hashing for applications where evaluation speed (∼10 ns vs. ∼140 ns) is prioritized over theoretical optimality. □

Remark 25 (Hash family selection guideline)**.** *Based on our 51-algorithm evaluation:*

- *Use **Siegel** ($k \geq 8$) when theoretical guarantees matter and n is large enough to amortize the evaluation cost.*
- *Use **tabulation** when n is moderate ($\leq 10^5$) and the application involves irregular access patterns (graphs, strings).*

- *Use **2-universal** only for algorithms with provably regular access patterns where the weaker concentration suffices.*
- ***MurmurHash3** is not recommended for applications requiring formal guarantees but performs acceptably in practice.*
- ***Identity** hashing provides no benefit and serves only as an ablation baseline.*

K Fixed-k Regime Analysis

When the independence parameter k is fixed (rather than growing with n), the overflow guarantee weakens from $O(\log n/\log\log n)$ to polynomial in n. We characterize this regime precisely.

Proposition 26 (Fixed-k overflow bound)**.** *Let $h : [n] \to [m]$ be drawn from a k-wise independent family with $k \geq 4$ even, and let $m = \lceil n/B \rceil$. The smallest overflow t^* such that $\Pr[\exists j : |h^{-1}(j)| \geq B + t^*] \leq 1/n$ satisfies:*

$$t^* = \Theta\big(\sqrt{kB} \cdot (n^2/B)^{1/k}\big) = \Theta\big(\sqrt{kB} \cdot n^{2/k}/B^{1/k}\big).$$

For $k = 8$ and $B = 8$:

$$t^* = \Theta(8 \cdot n^{1/4}/8^{1/8}) = \Theta(6.2 \cdot n^{1/4}).$$

Proof. From Lemma 12, the per-bin probability is $(kB/t^2)^{k/2}$. The union bound over $m \leq n/B$ bins requires:

$$\frac{n}{B} \cdot \left(\frac{kB}{t^2}\right)^{k/2} \leq \frac{1}{n}.$$

Solving: $\left(\frac{kB}{t^2}\right)^{k/2} \leq \frac{B}{n^2}$, so $\frac{kB}{t^2} \leq \left(\frac{B}{n^2}\right)^{2/k}$, giving $t^2 \geq kB \cdot (n^2/B)^{2/k}$, hence $t^* = \sqrt{kB} \cdot (n^2/B)^{1/k}$. □

Table 11: Theoretical vs. empirical overflow for fixed $k = 8$, $B = 8$. The SSS bound is extremely conservative; empirical overflow is < 10 at all tested sizes.

n	**SSS bound t^***	**Empirical max overflow**
256	25	< 4
1,024	35	< 5
4,096	50	< 6
16,384	70	< 7
65,536	99	< 10

Remark 27 (Theory-practice gap)**.** *The $> 10\times$ gap between the worst-case SSS bound and empirical behavior has two explanations: (1) the SSS moment-method bound loses tightness by applying Markov's inequality to a high moment, whereas the actual tail decays faster; (2) real PRAM algorithms produce address patterns with significant locality, making the adversarial "all addresses uniformly random" worst case unrealistically pessimistic. The adaptive independence selector closes this gap theoretically by choosing $k = O(\log n/\log\log n)$, at the cost of $O(n^{1/k})$ space for the Siegel family representation.*

L Data-Dependent Chain Analysis

A critique of the fixed-k regime is that k-wise independence may not suffice when the PRAM algorithm's access pattern exhibits *data-dependent chains*—sequences of memory accesses where address a_{i+1} depends on the value read at address a_i (e.g., pointer-chasing in graph algorithms).

Definition 28 (Data-dependent access chain)**.** *A* data-dependent chain *of length ℓ in a PRAM computation is a sequence of memory accesses $a_1, a_2, \ldots, a_\ell$ where for each $i \geq 2$, the address a_i is a function of the value stored at a_{i-1}.*

Proposition 29 (Hash-partition correctness under data-dependent chains)**.** *The hash-partition scheme is correct (preserves semantics) for data-dependent chains regardless of k. The overflow bound applies per-step, not per-chain: at each PRAM step t, the addresses accessed are determined by the algorithm state at step $t-1$, and the hash function is applied independently to each step's address set.*

Proof. Data-dependent chains affect which addresses are accessed but not the distribution of hash values. The hash function h is chosen once before execution; the k-wise independence guarantee applies to any fixed set of $\leq k$ addresses, regardless of how those addresses were computed.

The key observation is that the overflow analysis (Lemma 12) bounds the load of each bin considering all n addresses simultaneously. Within a single PRAM step, at most p addresses are accessed. If $p \leq k$, these p hash values are fully independent (since the family is k-wise independent), and the standard Chernoff bound applies. If $p > k$, the SSS bound applies as before.

For data-dependent chains spanning multiple steps, the sequential nature of the Brent schedule ensures that each step's accesses are resolved before the next step begins. The hash-partition maps each step's addresses to blocks, and the cache-miss analysis sums across steps. The data dependence does not introduce correlations in the hash values beyond what the k-wise independence already accounts for. □

Remark 30 (Practical impact on graph algorithms)**.** *The 8 graph algorithms in the benchmark suite (Shiloach–Vishkin, BFS, Borůvka MST, etc.) all involve data-dependent pointer-chasing. Their cache bound ratios (0.12 average for graph family, Table 9) are comparable to algorithms without data dependence, confirming that hash-partition handles data-dependent chains effectively in practice. The adaptive partitioner's GraphTraversal classification doubles block sizes for these algorithms, improving spatial locality for pointer-chasing access patterns.*
